ABSTRACT

This paper describes a spoken document retrieval system, combining the ABBOT large vocabulary continuous speech recognition (LVCSR) system developed by Cambridge University, Sheffield University and SoftSound, and the PRISE information retrieval engine developed by NIST. The system was constructed to enable us to participate in the TREC 6 Spoken Document Retrieval experimental evaluation. Our key aims in this work were to produce a complete system for the SDR task, to investigate the effect of a word error rate of 30-50% on retrieval performance and to investigate the integration of LVCSR and word spotting in a retrieval task.

1. INTRODUCTION

The area of spoken document retrieval, incorporating continuous speech recognition and information retrieval, is starting to receive considerable attention [1, 2]. This paper describes a spoken document retrieval system, combining the ABBOT LVCSR system developed by Cambridge University, Sheffield University and SoftSound, and the PRISE information retrieval engine developed by NIST. The system was constructed to enable us to participate in the TREC 6 Spoken Document Retrieval experimental evaluation. The system allowed us to transcribe a corpus of spoken documents at the word level using ABBOT, and to index the resulting text transcriptions using PRISE.

The LVCSR system uses a recurrent network-based acoustic model (with no adaptation to different conditions) trained on the 50 hour Broadcast News training set, a 65,000 word vocabulary and a trigram language model derived from Broadcast News text. Words in queries which were out-of-vocabulary (OOV) were word spotted at query time (utilizing the posterior phone probabilities output by the acoustic model), added to the transcriptions of the relevant documents and the collection was then re-indexed. We generated pronunciations at run-time for OOV words using the Festival TTS system (University of Edinburgh).

Our key aims in this work were to produce a complete system for the SDR task, to investigate the effect of a word error rate of 30-50% on retrieval performance and to investigate the integration of LVCSR and word spotting in a retrieval task. To achieve this we performed four basic experiments indexing on: transcribed text; baseline recognizer SRT files supplied by NIST; ABBOT SRT files; and ABBOT SRT files combined with word spotting of OOV words in the query.

This evaluation provided a stress test for our LVCSR system. In particular we developed our decoding algorithm and software to operate in a more "online mode". The result of this was the ability to decode arbitrarily long passages without segmentation into "utterances". When indexing, acoustic model computation required around $3.5\times$ real time on a Sun Ultra 1/170, and lexical search required around $2.5\times$ real time. At query time the word spotting component ran in about $0.25\times$ real time per document per query.

2. SYSTEM ARCHITECTURE

The outline of the basic system is illustrated in figure 1. The ABBOT LVCSR system was used to provide approximate transcriptions of the audio documents so that the task could be treated as one of text retrieval. Since the current ABBOT system uses a finite vocabulary of around 65,000 words, a query-time word spotter was incorporated to allow words that were OOV with respect to the LVCSR system to be retrieved.

Figure 1: The indexing portion of the THISL Spoken Document Retrieval system used in TREC-6.

3. THE ABBOT LVCSR SYSTEM

ABBOT is a hybrid connectionist/HMM system [3] that differs from traditional HMMs in that the posterior probability of each phone given the acoustic data is directly estimated at each frame, rather than the likelihood of a phone (or state) model generating the data. This posterior probability estimation is achieved by using a connectionist network trained as a phone classifier. In the ABBOT system, a recurrent network [4] is used as the acoustic model. Direct estimation of the posterior probability distribution using a connectionist network is attractive since fewer parameters are required for the connectionist model (the posterior distribution is typically less complex than the likelihood) and connectionist architectures make very few assumptions on the form of the distribution. Additionally, this approach allows for an efficient search algorithm that uses a posterior probability-based pruning (section 3.3) [5] and is able to provide useful acoustic confidence measures [6].

Since the likelihood is required in the decoding process, the posterior is converted to a scaled likelihood, $L(x;q)$. This may be computed by dividing the posterior probability estimate of the phone (or HMM state) q given the data x , by the class prior $P(q)$ estimated as the relative frequency in the training data:

$$L(x;q) = \frac{P(q|x)}{P(q)} = \frac{p(x|q)}{p(x)}. \quad (1)$$

The assumptions underlying this acoustic model are discussed in detail in [3, 7].

3.1. Acoustic Model

The acoustic model used in the THISL system consisted of two recurrent networks with 53 context-independent phone classes (plus silence). One network estimated the phone posterior probability distribution for each frame given a sequence of 12th order perceptual linear prediction features [8]. The other network performed the same distribution estimation with features presented in reverse order (since recurrent networks are time-asymmetric) and the two probability estimates were averaged in the log domain.

The context independent probability estimates $P(q|x)$ were combined with a context class posterior probability $P(c|q,x)$, where c is an acoustic context class, to give the joint posterior probability of context class and phone class, $P(q,c|x) = P(q|x)P(c|q,x)$ [9, 10]. The context classes were estimated using a decision tree algorithm and the context class posterior was estimated using a single layer network for each phone class. A total of 604 context-dependent phone models were used. This system is described in greater detail in [11].

The acoustic models were trained by a Viterbi training procedure using the Broadcast News acoustic training data at all focus conditions.

3.2. Language Model

The system used a 65,532 word vocabulary prepared by selecting the 80,000 most frequent words from the broadcast news text data and removing misspellings, processing errors, etc. A backed-off trigram language model was built from the Broadcast News text data (132 million words), resulting in test set perplexities typically in the range 200–300.

3.3. Search

The TREC/SDR evaluation provided a stress test for our recognition system, since it involved performing LVCSR over the broadcast archive (around 39 hours of speech), with some “segments” of speech up to one hour long. We have extended the NOWAY start-synchronous decoder [12], to operate in an “online” mode, decoding arbitrarily long streams of speech without an additional CPU or memory burden.

NOWAY is based on a stack decoder framework and exploits the acoustic model posterior probability estimation in an effective pruning technique referred to as phone deactivation pruning [5]. This single pass algorithm is naturally factored into time synchronous state-level processing and time asynchronous word-level processing. This enables the search to be decoupled from the language model. Incremental output of the most probable final transcription is possible owing to the tree structuring of the search and the domination of language model equivalent paths.

In this evaluation, using posterior probability based phone deactivation pruning, the usual beam pruning and a unigram language model approximation at the state level we were able to decode the evaluation broadcast archive with an average of less than 1,500 model evaluations per frame (corresponding to a run time of less than 6× real time on a Sun Ultra 1/170).

4. THE PRISE INFORMATION RETRIEVAL ENGINE

Version 2.0 of the PRISE system [13] was used as the information retrieval engine for this experiment. PRISE compares the similarity of a document to a query by summing the weights of all the matching terms. The weights are calculated using an inverse document frequency measure. The system was used as supplied with no modifications and the standard PRISE stop list of 23 words and the SMART stemming algorithm were used.

5. RAPID WORD SPOTTING USING POSTERIOR PROBABILITIES

CSR systems can only recognize words which are contained in their lexicon. Although the ABBOT system used for these experiments had a 65k word vocabulary, approximately 1% of the words in the test set were out of vocabulary (OOV).

This raises a potential problem at the information retrieval stage: infrequent words are potentially important during retrieval but such words are most likely to be OOV. This could have a deleterious effect on performance. To counteract this, a rapid word spotting module was added to the system to try and find any OOV query words.

The queries were scanned for OOV words. Any OOV words for which pronunciations did not exist were sent to an automatic pronunciation generator using the letter-to-sound rules in the Festival speech synthesis system [14].

The word spotting module used the context-independent posterior probability estimates from the recurrent network acoustic model, dynamically constructing word models for target words and using a set of looped phone garbage models. Any spotted words were added into the appropriate section of the speech recognition transcription. The transcriptions were then re-indexed and the standard retrieval procedure followed¹.

In the event, the only OOV word in the test queries was ‘CIA’ (ABBOT treats each letter of an abbreviation as a separate word and was thus expecting C. I. A.). Furthermore, no instances of it were found by the word spotting module (because it treated it as a word rather than a string of letters). Consequently, the word spotting module had no impact on system performance during this experiment.

6. THE TREC 6 SPOKEN DOCUMENT RETRIEVAL EXPERIMENT

The TREC 6 Spoken Document Retrieval (SDR) experiment was designed to compare different combinations of speech recognition and information retrieval systems. The task was to retrieve a set of spoken documents which were the targets of 49 text queries. The spoken documents were news items from the Broadcast News corpus. The test set consisted of 85 different broadcasts subdivided into 1451 different sections (documents)² comprising 39 hours of speech. The test documents ranged in duration from one second to 36 minutes in length with an average of 96 seconds.

In response to a query, each system had to produce a ranked list of documents which could then be scored. Two scoring measures were used: Expected Run Length and Mean Reciprocal.

Expected Run Length is simply the mean rank at which the target documents were found across the 49 queries:

$$E = \frac{1}{N} \sum_{i=1}^N r_i \quad (2)$$

where N is the number of queries and r_i is the rank at which document i was retrieved. During the experiment, if a document was not found in the first 1000, it was assigned a score of 2000. Good system performance is reflected by a low Expected Run Length.

Mean Reciprocal is the mean of the reciprocal of the rank at which the target documents were found across the 49 queries:

$$E = \frac{1}{N} \sum_{i=1}^N \frac{1}{r_i} \quad (3)$$

¹Obviously, this technique could not be used on a large corpus or in a practical system, but it can help to give an indication of the importance of OOV words

²Some types of item were not used in the experiment, e.g. commercials, weather forecasts, sports and local news.

The Mean Reciprocal measure has an advantage over Expected Run Length as it minimizes the difference between a document retrieved in 100th position and one retrieved in 350th — neither position would be much good in practical terms — whilst emphasizing the importance of getting a low retrieval rank. Mean Reciprocal ranges between 0 and 1 and a good system performance is reflected by a high value.

The experiment consisted of four different runs in which indexing was performed on text transcriptions of the broadcasts, SRT files from a baseline recognizer supplied by NIST, SRT files from ABBOT, and the ABBOT SRT files augmented with the results from word spotting of OOV query words. For the reasons outlined in section 5, the two ABBOT runs produced identical results. The transcribed text run enabled comparisons to be made with respect to a perfect speech recognizer. The baseline recognizer transcriptions were provided essentially to enable IR labs with no speech recognition capability to participate in the experiment, but also facilitated analysis of the contribution made by the speech recognition component to the overall system.

7. EXPERIMENTS

7.1. Speech Recognition Performance

We applied the ABBOT system to the SDR test data, consisting of around 50 hours of Broadcast News, of which around 39 hours needed to be recognized. Table 1 shows the word error rate (WER) for this data set, broken down into the seven focus conditions.

Table 1: ABBOT Performance at the Broadcast News Focus Conditions

Focus	Description	WER
F0	Baseline Broadcast Speech	24.9%
F1	Spontaneous Broadcast Speech	43.2%
F2	Speech / Telephone Channels	50.8%
F3	Speech / Background Music	49.4%
F4	Speech / Degraded Acoustic Conditions	35.5%
F5	Speech / Non-Native Speakers	36.3%
FX	All other speech (combinations)	55.7%
-	Overall	40.1%

We estimate the relative search error (introduced by pruning) to be around 15%. This was very much a baseline system — only data from the F0 condition was used for training, and no attempt was made to segment out non-speech portions (e.g., music) resulting in an increased number of insertions.

7.2. IR Performance

We compared the performance of the system using the supplied transcript, the supplied output of the baseline recognizer and the output of the ABBOT recognizer. These results are summarized in table 2.

Table 2: Results using the PRISE IR System

Transcription	Mean Rank	Mean Reciprocal
Reference	11.59	0.6236
Baseline Recognizer	30.43	0.5062
ABBOT LVCSR	27.82	0.5784

We have analysed the IR performance with respect to the WER and the focus conditions. Figure 2 shows a scatter plot of retrieval

rank versus WER for the baseline and ABBOT recognizers using PRISE for the 49 retrieved target sections. The plot suggests that there is a good chance of obtaining a low retrieval rank if the WER of the target section is less than about 40%.

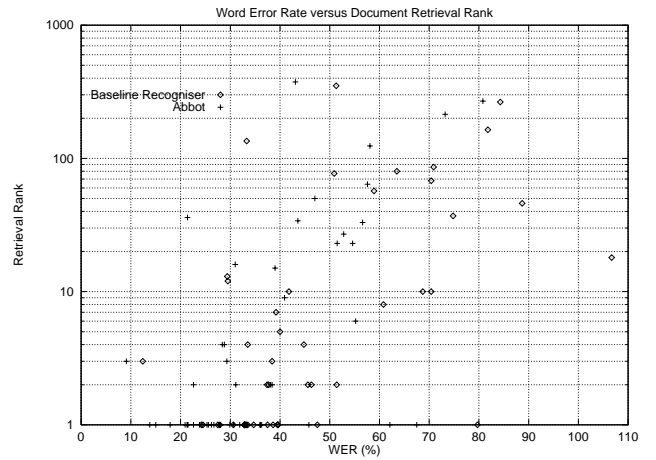

Figure 2: Mean reciprocal retrieval performance vs. WER.

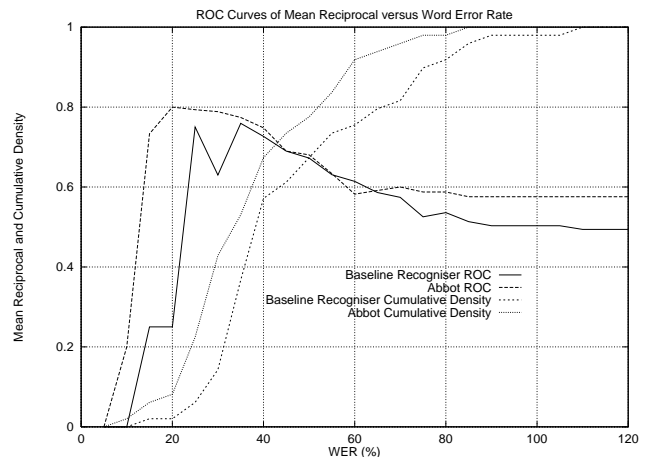

Figure 3: Mean reciprocal retrieval performance vs. WER.

Figure 3 graphs the mean reciprocal retrieval performance against the WER for both recognizers. Also plotted are the cumulative WER distributions for each recognizer. In this case the WER was used as a rejection threshold, and only those documents (and corresponding queries) with a WER below that threshold were considered. For the ABBOT system, about 65% of documents had a WER of 40% or less, and using those documents the mean reciprocal ranking for retrieval was around 0.75. The ROC curves reinforce the message of the scatter plot: that performance begins to fall sharply if the WER of the target document is over 40%.

Figure 4 graphs the mean reciprocal ranking against the WER for target sections containing speech largely from the F0 and FX focus conditions (twelve of each). It shows a similar picture to Figure 3: retrieval performance is good when WER is below 40%, above this figure it begins to deteriorate. Most of the F0 target sections had low WER resulting in an overall mean reciprocal fig-

Figure 4: Mean reciprocal retrieval performance vs. WER for THISL system for target sections at F0 and FX focus conditions.

ure of 0.8 whereas some of the FX target sections had high WER contributing to an overall mean reciprocal figure of 0.6.

8. CONCLUSION

Our principal goal in this evaluation was to develop a working spoken document retrieval system, and to apply our recognizer to tens of hours of broadcast speech data. We have succeeded in this objective. Future work will involve development of IR methodologies for spoken document retrieval (rather than treating the problem as text retrieval and using an “out-of-the-box” system) and to further improve the speech recognition component.

9. ACKNOWLEDGMENTS

Thanks to Tony Robinson of SoftSound and Cambridge University Engineering Department for his contribution to the paper. Thanks also to Paul Over, John Garofolo and Ellen Voorhees of NIST for help and advice with the PRISE system and the TREC evaluation. Thanks also to Alan Black of the University of Edinburgh for assistance with the Festival system.
