## ABSTRACT

In this paper, a fast motion estimation algorithm, which is friendly to VLSI hardware implementation is proposed. This algorithm has such features: First, through "Haar" low-pass filter based subsampling, the computation complexity at each search position is reduced to about 25% of the original algorithm; Second, one modified motion vector prediction is provided to eliminate the data dependence among sub-partitions in the same macro block(MB). Based on this approach, parallel processing for variable block size motion estimation(VBSME) with integer pixel accuracy can be realized; Third, one "adaptive sub-search window" scheme is proposed to further reduce computation cost and it also can facilitate reference frame data reusing to reduce memory transfer from the external RAM to the onchip SRAM. The proposed VBSME algorithm is very suitable for parallel VLSI implementation.

### 1. INTRODUCTION

H.264/AVC is the newest international video coding standard, which can provide much better peak signal-to-noise (PSNR) and visual quality [1]. In H.264/AVC, motion estimation (ME) is conducted on different blocks sizes named as VBSME. During VBSME, all the block sizes inside one MB are processed and the block mode with the best R-D cost is then chosen. Compared with previous fixed block size ME process, VBSME can achieve higher compression ratio and better video quality, but it accounts for more than 50% computation cost of the encoding algorithm. Therefore, hardware acceleration is a must for real-time applications. How to reduce the processing time and power dissipation of VBSME is a vital issue for real-time encoder and this needs hardware-software co-optimization. Computation complexity reduction, simple control logic and regular memory access are three important issues for hardware architecture design. Many fast motion estimation algorithms have be provided to reduced the algorithm computation through reducing search positions. These algorithms are efficient for fixed block ME. But for H.264, because MB is partitioned into many blocks and each block has its own search path, it is hard for fast ME to realize SAD reusing scheme as full search (FS) algorithm [2]. Partition mode in H.264 multiplies the computation complexity of fast ME. In real-time applications, worst-case complexity of a ME method becomes more important than its average complexity. Despite improving average complexity, fast ME techniques won't have much better worst-case complexity than FS with SAD reuse. Moreover, the control logic and

Yang Song, Takeshi Ikenaga, Satoshi Goto

The Graduate School of IPS Waseda University Kitakyushu, 808-0135, Japan

memory access of fast ME are complex and irregular, so they are not suitable for hardware designs. In fact, FS is more preferred in hardware ME accelerator designs, because (1) Process elements (PE) are scheduled to work in parallel and fully utilized, so its throughput is in direct ratio to its PE number; (2) Its memory access and control logic are regular and simple; (3) It can realize SAD reusing scheme in H.264, so the computation complexity is almost reduced to the level of single block type case. In order to apply FS to built parallel hardware accelerator, two problems must be resolved. First, the data dependency in one MB must be eliminated to make parallel processing feasible. Second, the computation complexity must be reduced to save its hardware cost, power dissipation and processing latency.

In this paper, we provide a low-pass filter based subsampling algorithm and sub-search window approach to reduce the computation. In order to eliminate the data dependency, one simplified motion vector prediction (SMVP) algorithm is proposed to facilitate parallel processing. The details of this algorithm are described in Section 2. The simulation results in Section 3 show that there is little quality loss, despite a major reduction in complexity. Conclusions are given in Section 4.

## 2. LOW-PASS FILTER BASED VLSI ORIENTED VBSME ALGORITHM

#### 2.1. Low-Pass Filter Based Subsampling Algorithm

Subsampling is one effective approach for arithmetic computation reduction. During ME procedure, the search area data and current MB are both subsampled in vertical direction [3], so 50% arithmetic computation can be reduced. What is more, because this approach does not increase the complexity of control logic and memory access, it is widely applied in hardware accelerator. But directly subsampling algorithm also brings some problems. First it causes signal distortion. For 1-D signal x(n), its frequency spectrum is denoted as  $X(e^{j\omega})$ . The subsampled signal y(n) and its frequency spectrum  $Y(e^{j\omega})$  can be represented as Eq. 1 and Eq. 2.

$$y(n) = x(2n) \tag{1}$$

$$Y(e^{j\omega}) = \frac{1}{2} [X(e^{j\frac{\omega}{2}}) + X(e^{j(\frac{\omega}{2} - \pi)})]$$
(2)

This procedure is also clearly illustrated in Figure 1. We can see that the frequency aliasing after subsampling causes the distortion of the signal.

The second drawback of subsampling is that small blocks are more prone to be trapped into false optimal points. In H.264, there

<sup>\*</sup>Thanks to Kitakyushu knowledge-based cluster project for the Japanese Ministry of ECSST funding.

Fig. 1. Frequency Aliasing after Subsampling

exists small size blocks, such as  $4 \times 4$  and  $4 \times 8$  blocks. After subsampling, most characters of these small blocks are lost. For example, if the picture is decimated in both vertical and horizonal directions, each  $4 \times 4$  block has just 4 pixels. During ME, 4-pixel data character makes  $4 \times 4$  blocks more prone to false optimal points.

For one image, low-frequency signals contain more information than high frequency signals. Moreover, after motion-compensated prediction, the low-frequency DCT coefficients of the residual data are more significant, because high frequency coefficients are always discarded during quantization procedure. Based on this hypothesis, we could applied subsampling approach on the low-frequency signals of the video sequence. In details, the reference picture and the current picture first pass through a low-pass filter to get low frequency signals, which are labelled as low-frequency reference (LR) and low-frequency current (LC). Subsampling ME algorithm is processed on these low-frequency pictures. Because the high frequency signals are filtered, the frequency aliasing can be greatly alleviated. Moreover, through the low-pass filter, the word-length of each pixel is increased, so more characters are preserved. Consequently, Lowpass filter based subsampling algorithm can efficiently resolve those problems caused by directly subsampling.

In order to reduce the computation burden, we apply "Haar" low-pass filter, which means that each pixel in the generated picture is the sum of neighboring four pixels in the source picture. For example, the pixel LR(i, j) can be expressed as Eq. 3.

$$LR(i,j) = R(i,j) + R(i+1,j) + R(i,j+1) + R(i+1,j+1)$$
(3)

In SAD calculation, LR and LC are subsampled in both horizonal and vertical directions. The SAD computation of a  $B_x \times B_y$  size block with the  $(l_x, l_y)$  coordinate in the frame can be expressed as Eq. 4, where (u, v) represents the motion vector. So, at each search position, the processed pixel number is reduced to 25% of full-search algorithm. Different from wavelet based ME, we do not decimate the LR frame, so (u, v) traverses each search position in the search window. Though wavelet based ME can further reduce the computation through decreasing search positions, it has two drawbacks for VB-SME in H.264: (1) The search step based on decimation is 2-pixel. After coarse search, each block must search around its coarse search result to find its 1-pixel accuracy optimal position. Because there are 41 blocks in one MB, it is not easy to realize one efficient hardware for this refining search. (2) Decimating both LR and LC causes shift variance problem [4]. This problem is more serious for small size blocks.

Fig. 2. RD performances for Foreman CIF sequence at 30fps

In order to investigate the low-pass filter based subsampling VB-SME algorithm, it is compared with FS and directly subsampling algorithm. The first 255 frames in "foreman" CIF sequence are used in the simulation. The test conditions are I-P-P-M, CAVLC, Hadamard transform,  $32 \times 32$  search range, R-D optimization and 5 reference frames. The RD-curves are shown in Figure 2. Compared with FS algorithm, directly subsampling algorithm has about 0.15dB PSNR loss. In contrast, the subsampling based on "Haar" low-pass filter has the similar performance as FS algorithm.

If the picture width is W, the picture hight is H and the search range is  $M \times N$ , in the original FS algorithm for each reference frame, the absolute difference (AD) number is  $W \times H \times M \times N$  and the addition operation (ADD) number is  $W \times H \times 265 \times M \times N/256$ . In our algorithm, the ADD number for low-pass filter of each reference frame is  $4 \times W \times H$ . After subsampling in vertical and horizonal directions, for each search position's SAD calculation, the AD number is  $(W \times H \times M \times N \times 64)/256$ . Taking the low-pass filter processing into account, the total ADD operation is  $W \times H \times (73 \times M \times N/256+4)$ . If search rang is  $32 \times 32$ , compared with FS VBSME, 75% AD and 72% ADD operations can be saved by our algorithm during SAD cost computation.

#### 2.2. Simplified Motion Vector Prediction Algorithm

In the reference encoder software, RD cost is the sum of SAD and encoding cost of motion vector difference (MVD). MVD calculation incurs data dependency among not only adjacent MBs but also subpartitions within one MB. This makes parallel processing unfeasible. To eliminate the data correlation within MB, the approach in reference [2] is directly omitting the MVD cost during the integer pixel precision VBSME, because SAD cost is much more important than MVD cost. Based on this modified algorithm, high performance 2-D [2] and 1-D [5] array processing VBSME architectures are proposed. Unfortunately, this scheme is not suitable for our algorithm. First, the low-pass filter makes the video lose its high frequency signals. Second, subsampling incurs the frequency aliasing noise. Third, after subsampling, feature loss is serious for small blocks, which makes they prone to be trapped in false optimize search positions. Through experiments, we find that without MVD cost our algorithm has 0.3dB-0.6dB PSNR loss.

Fig. 3. Lables of Macroblock and sub-macroblock partitions

One modified MVP algorithm, which avoids the data dependency within MB, is provided in this paper to facilitate VBSME parallel processing. In order to clarify the algorithm, 41 blocks in one MB are labelled, as shown in Figure 3. Considering pipeline processing and hardware complexity, we just use MVs of the four  $4 \times 4$ blocks in the upper neighboring MB to derive MVPs of all blocks in current MB, as shown in Figure 4.

Fig. 4. Motion Vector Prediction Data Dependency

If "Upper MB" exits, the MVP for blocks " $4 \times 4.0$ ", " $4 \times 4.4$ ", " $4 \times 4.8$ ", " $4 \times 4.12$ ", " $4 \times 8.0$ " and " $4 \times 8.4$ " is  $\overrightarrow{MV}_{4 \times 4.4}$ ; the MVP for blocks " $4 \times 4.1$ ", " $4 \times 4.5$ ", " $4 \times 4.9$ ", " $4 \times 4.13$ ", " $4 \times 8.1$ " and " $4 \times 8.5$ " is  $\overrightarrow{MV}_{4 \times 4.8}$ ; the MVP for blocks " $4 \times 4.2$ ", " $4 \times 4.6$ ", " $4 \times 4.10$ ", " $4 \times 4.14$ ", " $4 \times 8.2$ " and " $4 \times 8.6$ " is  $\overrightarrow{MV}_{4 \times 4.2}$ ; the MVP for blocks " $4 \times 4.3$ ", " $4 \times 4.7$ ", " $4 \times 4.11$ ", " $4 \times 4.15$ ", " $4 \times 8.3$ " and " $4 \times 8.7$ " is  $\overrightarrow{MV}_{4 \times 4.0}$ ; the MVP for blocks " $8 \times 4.0$ ", " $8 \times 4.4$ ", " $8 \times 4.6$ ", " $8 \times 8.0$ ", " $8 \times 8.2$ " and " $8 \times 16.0$ " is ( $\overrightarrow{MV}_{4 \times 4.4} + \overrightarrow{MV}_{4 \times 4.8}$ )/2; the MVP for blocks " $8 \times 4.1$ ", " $8 \times 4.3$ ", " $8 \times 4.5$ ", " $8 \times 4.7$ ", " $8 \times 8.1$ ", " $8 \times 8.3$ " and " $8 \times 16.1$ " is ( $\overrightarrow{MV}_{4 \times 4.2} + \overrightarrow{MV}_{4 \times 4.2}$ )/2; the MVP for blocks " $16 \times 8.0$ ", " $16 \times 8.1$ " and " $16 \times 16.0$ " is ( $\overrightarrow{MV}_{4 \times 4.4} + 4.4 \times 4.4 \times$ 

## 2.3. Adaptive Sub-Search Window

In H.264 encoder reference software, each block uses its MVP as search window center. That means each block has its own dedicated search window. In the view point of the hardware implementation, it is highly preferred to the uniform search window for all blocks in MB, because SAD reusing scheme can be fully utilized. In order to simplify the control logic and the data transfer, rectangle search area is preferred. In reference [2], [0, 0] is adopted as uniform search

window center because this approach can facilitate data reusing to reduce data transfer. For those sequences which have large MVs, the real MVs will be out of the range of search window. Certainly, we can enlarge the search window to resolve this problem, but this approach incurs the increase of computation complexity, internal memory access and power dissipation. These items increase in direct ratio to the search area.

In order to resolve this problem, we provide an adaptive subsearch window scheme. First we define the search area frame for each MB. The search frame center is [0, 0], so its overlapped area for adjacent MBs can be reused as reference [2]. The search frame width is denoted as  $F_w$  and its hight is denoted as  $F_h$ .  $F_w$  and  $F_h$  could be defined large enough to cover the real MV. VBSME is just performed in a sub-area in the search frame, which is derived from  $\overrightarrow{MV}_{4\times 4.A}$  $\overrightarrow{MV}_{4\times 4.B} \ \overrightarrow{MV}_{4\times 4.C}$  and  $\overrightarrow{MV}_{4\times 4.D}$ . The bottom left corner of this sub-area is  $[x_{bl}, y_{bl}]$  and the top right corner is  $[x_{tr}, y_{tr}]$ , which are defined in Eq. 5. This scheme dramatically reduces the search positions even the video sequence has large MVs. For example, using "stefan" CIF first 255 frames, if  $F_w = F_h = 64$ ,  $x_e = y_e = 16$ , the average searched positions just account for 28.7% of the search frame.

$$\begin{cases} x_{bl} = \max(-F_w/2, \min(\overrightarrow{MV}_{4\times4,A}[x], \overrightarrow{MV}_{4\times4,B}[x], \\ \overrightarrow{MV}_{4\times4,C}[x], \overrightarrow{MV}_{4\times4,D}[x]) - x_e) \\ y_{bl} = \max(-F_h/2, \min(\overrightarrow{MV}_{4\times4,A}[y], \overrightarrow{MV}_{4\times4,B}[y], \\ \overrightarrow{MV}_{4\times4,C}[y], \overrightarrow{MV}_{4\times4,D}[y]) - y_e) \\ x_{tr} = \min(F_w/2, \max(\overrightarrow{MV}_{4\times4,A}[x], \overrightarrow{MV}_{4\times4,B}[x], \\ \overrightarrow{MV}_{4\times4,C}[x], \overrightarrow{MV}_{4\times4,D}[x]) + x_e) \\ y_{tr} = \min(F_h/2, \max(\overrightarrow{MV}_{4\times4,A}[y], \overrightarrow{MV}_{4\times4,B}[y], \\ \overrightarrow{MV}_{4\times4,C}[y], \overrightarrow{MV}_{4\times4,D}[y]) + y_e) \end{cases}$$

## 3. EXPERIMENTAL RESULTS

The experimental conditions are shown in Table 1 and the relative results are shown in Table 2. For the evaluation of the proposed algorithm performance, we test the FS algorithm in reference software (Jm81a) and the simplified full search (SFS) algorithm provided in [2]. BDBR (Bjonteggard Delta BitRate) and BDPSNR (Bjonteggard Delta PSNR) [6], which are respectively average difference of bitrate and PSNR between two methods, are used and they are derived from the simulation results when QP = 28, 32, 36, 40. FS of Jm81a is adopted as norm. The BDBR and BDPSNR results are shown in Table 3. The (+) sign in BDBR and (-) sign in BDP-SNR indicate the coding loss. From Table 3 we observe that our

algorithm and SFS have the similar performance as reference FS. In most sequences, our scheme is better than SFS except for "coastguard" and "stefan". The higher coding loss in "stefan" sequence is caused by the limitation of sub-search area. If  $x_e$  and  $y_e$  are extend to  $x_e = y_e = 24$ , significant quality gain can be observed. For "coastguard", it contains a lot of high frequency signals because its background includes a river. So the low-pass filter reduces the VB-SME's quality.

In these simulations, our algorithm needs much less computation operations in integer pixel accuracy VBSME. For example, in "tempete" sequence, the searched points of our algorithm is 28.6% of SFS's and at each position the "AD" operation number is just 25% of SFS's, so the total "AD" operation of our algorithm is 7.15% of SFS's.

Table 3. Performance Comparison in BDBR and BDPSNR

|            | SF     | S[2]     | Proposed |          |  |  |
|------------|--------|----------|----------|----------|--|--|
|            | BDBR   | BDPSNR   | BDBR     | BDPSNR   |  |  |
| foreman    | +3.36% | -0.167dB | +1.26%   | -0.064dB |  |  |
| carphone   | +2.57% | -0.122dB | +1.40%   | -0.067dB |  |  |
| news       | +1.86% | -0.107dB | +0.90%   | -0.053dB |  |  |
| coastguard | +0.60% | -0.021dB | +1.10%   | -0.038dB |  |  |
| stefan     | +1.87% | -0.094dB | +2.70%   | -0.136dB |  |  |
| tempete    | +1.48% | -0.062dB | +0.80%   | -0.032dB |  |  |

## 4. CONCLUSIONS

One VLSI parallel processing oriented integer pixel accuracy VB-SME algorithm is provided in this paper. Three major approaches are proposed. First, low-pass filter based subsampling scheme effectively reduces about 75% arithmetic operations in every "SAD" calculation with trivial coding efficiency loss. Similar to FS algorithm, SAD reusing scheme can be adopted by our algorithm to reduce the computation cost more. Second, the SMVP algorithm avoids the data dependency among sub-partitions within one MB and this makes VLSI parallel processing feasible. At last, the proposed subsearch window could efficiently reduces the search positions. Consequently, the power consumption for integer pixel accuracy VBSME could be reduced in ratio to the average search area. Compared with the original FS, this algorithm has considerably lower complexity and it is much more suitable for parallel processing VLSI implementation.
