# RECONSTRUCTION OF SIGNALS FROM HIGHLY ALIASED MULTICHANNEL SAMPLES BY GENERALIZED MATCHING PURSUIT

Massimiliano Vassallo, Ali Özbek, Yousif Izzeldin Kamil, Dirk-Jan van Manen, Kurt Eggenberger Schlumberger

### ABSTRACT

In this paper we consider the problem of reconstructing a bandlimited signal from severely aliased multichannel samples. Multichannel sampling in this context means that the samples are available after the signal has been filtered by various linear operators. We propose the method of Generalized Matching Pursuit to solve the reconstruction problem. We illustrate the potential of the method using synthetic data computed for multimeasurement towedstreamer seismic data acquisition. A remarkable observation is that high-fidelity reconstruction is possible even when the data are uniformly and coarsely sampled, with the order of aliasing significantly exceeding the number of channels.

## **1. INTRODUCTION**

In multichannel sampling, samples of a signal that was filtered by various linear operators are available. Suppose m(y)=h(y)\*s(y), where m(y)=[m1,...,mJ] are the measurements, and h(y)=[h1,...,hJ] are the operators. The samples are available at points y1,...,yL, which may be regularly or irregularly spaced. The objective is to reconstruct bandlimited signal s(y) at arbitrary points y. In Figure 1, we show a slight generalization, where, for each channel j, the measurements are undersampled by a factor of  $R_j$  with respect to the bandwidth of s. In the spectral domain, we have  $m(k_y)=H(k_y)s(k_y)$ , where  $k_y$  is the wavenumber (spatial frequency).

Fig. 1. Multichannel sampling.

The generalized sampling expansion proposed by Papoulis [1] implies that such a linear system, under certain conditions, allows reconstruction of the desired signal when  $R_j=J$ , j=1,2,...J. However, Papoulis [1] does not provide a readily realizable solution for the inversion of the system.

Later, several articles were proposed to study the properties of the generalized sampling expansion, the well-posedness of the system, and a closed-form solution of the inverse problem [2, 3].

In some applications, such as towed streamer marine seismic data acquisition, the decimation rate  $R_j$  can be significantly larger than the number of channels, J. In this case the order of aliasing significantly exceeds the number of channels. In the next section, we discuss a method that has shown promising performance in this setting.

### 2. GENERALIZED MATCHING PURSUIT

In this section, we describe a parametric matching pursuit method to solve the reconstruction problem that arises in multichannel sampling; we call it *Generalized Matching Pursuit (GMP)*, as its aim is to reconstruct a signal of which no direct samples may be available. Suppose that the unknown signal s(y) is modeled as a sum of parametric basis functions  $\beta(y; \theta_n)$  with parameter set  $\theta_n$ :

$$s(y) = \sum \beta(y; \theta_n). \quad (1)$$

There are various basis functions that can be considered; one possibility that is especially convenient for seismic applications is

$$\beta(y;\boldsymbol{\theta}_n) = A_n \exp \left| j \left( k_{y,n} y + \boldsymbol{\phi}_n \right) \right|, \quad (2)$$

where the parameter set  $\theta_n$  consists of amplitude  $A_n$ , phase  $\phi_n$ , and wavenumber  $k_{y,n}$ . The corresponding measurements would then be

$$\boldsymbol{m}(\boldsymbol{y}) = \sum_{n} \boldsymbol{H}(\boldsymbol{k}_{\boldsymbol{y},n}) \boldsymbol{\beta}(\boldsymbol{y};\boldsymbol{\theta}_{n}).$$
(3)

In GMP, the forward linear filters  $H_j(k_y)$  are applied to each basis function; the filtered basis functions are then iteratively matched to the multichannel measurements. Iteratively, the basis function that, once forward filtered, jointly best matches all the input signals is used to reconstruct the desired output, with or without the forward filter applied. At the *N*-th iteration, i.e., after *N-1* basis functions have been determined previously, the residual in the measurements is given by

$$\boldsymbol{r}^{N-1}(\boldsymbol{y}) = \boldsymbol{m}(\boldsymbol{y}) - \sum_{n=1}^{N-1} \boldsymbol{H}(\boldsymbol{k}_{\boldsymbol{y},n}) \boldsymbol{\beta}(\boldsymbol{y};\boldsymbol{\theta}_n) .$$
(4)

If a new term  $\beta(y; \boldsymbol{\theta}_N)$  is added to the existing representation of the signal, the updated residual at the positions *y* becomes  $r^N(y; \boldsymbol{\theta}_N) = r^{N-1}(y) - H(k_{y,N}) \beta(y; \boldsymbol{\theta}_N)$ , where the parameters of the new term, i.e.,  $\boldsymbol{\theta}_N$ , are to be determined by minimizing a metric of the residual calculated over measurement locations. One such metric is

$$\mu(\boldsymbol{\theta}_{N}) = \sum_{l} \left[ \boldsymbol{r}^{N}(\boldsymbol{y}_{l};\boldsymbol{\theta}_{N}) \right]^{H} \boldsymbol{C}^{-1} \boldsymbol{r}^{N}(\boldsymbol{y}_{l};\boldsymbol{\theta}_{N}), \quad (5)$$

where the superscript *H* represents the Hermitian operator, *C* is a positive definite matrix, and  $y_l$  represents the sensor locations in the *y* direction. These locations can, in general, be irregularly spaced. The role of matrix *C* is to weight the contributions of different measurements to the cost function to be minimized. This can take into account the difference of energy content due to the different physics of the input measurements, as well as the signal-to-noise ratio that can vary in time, space, and frequency [10].

For basis functions chosen as in (2), it can be shown that the optimal  $A_N$  and  $\phi_N$  can be analytically related to the residuals  $\mathbf{r}_{N-1}$ , the input sample positions  $y_l$ , and the optimal wavenumber  $k_{y,N}$ . Hence, the only remaining parameter to select is

$$k_{y,N} = \arg\max_{k} \mathcal{L}\left\{A_{N}\left(\boldsymbol{r}^{N-1}(y_{l}), k\right), \boldsymbol{\phi}_{N}\left(\boldsymbol{r}^{N-1}(y_{l}), k\right)\right\}.$$
 (6)

We call the objective function  $\mathcal{L}$  the generalized Lomb spectrum, in analogy with the single-channel interpolation problem. There, in the case of sinusoidal basis functions, the objective function generated by *Interpolation by Matching Pursuit (IMAP)* with optimal amplitudes in the least-squares sense corresponds to the Lomb spectrum [4, 5, 6]. The GMP iterations can be terminated once the residual energy falls below a predetermined fraction of the input energy.

Next, we illustrate the antialiasing power of GMP for uniformly sampled multichannel data with a very simple multichannel sampling example. In this example, a single sinusoid signal with wavenumber 30 Km<sup>-1</sup> is uniformly sampled at 25 Km<sup>-1</sup>. In addition to the signal samples, the spatial gradient samples are available at the same locations. Due to uniform sampling, there is hard-aliasing, i.e., exact periodic replicas in the spectra of each channel. This is a reconstruction problem that cannot be solved by multichannel sinc interpolation [7], since the order of aliasing is greater than two. Figure 2 shows the cost function to select the optimum wavenumber (negative of the generalized Lomb spectrum) at the first iteration. The aliases of the correct wavenumber can be clearly seen. However, simultaneous use of the multichannel measurements in the optimization process results in the correct wavenumber being selected.

# **3. APPLICATION TO MULTICHANNEL SAMPLING**

Due to logistical and cost constraints, marine seismic acquisition systems can be deployed to acquire data only along a limited number of parallel lines (i.e., towed streamers) that are coarsely spaced in the crossline direction.

Fig. 2. Cost function for the optimum wavenumber in a hard-aliasing problem resulting from insufficient uniform sampling.

Streamers are towed typically with crossline spacing of 75-100 m, resulting in coarse wavefield sampling that contrasts with adequate (non-aliasing) wavefield sampling of 6.25 m along the streamers (inline). Consequently, they do not adequately capture the full spatial bandwidth of the subsurface-scattered wavefield, leading to limitations in accurate subsurface imaging. Furthermore, conventional (pressure-only data) acquisition systems suffer from the ghost effect. The ghost is the reflection from the sea surface that interferes constructively or destructively with the upgoing wavefield (the signal of interest for imaging), reducing the seismic bandwidth at the low and high ends of the spectrum. To address these critical limitations, a multimeasurement marine seismic acquisition platform was recently introduced. It is equipped with hydrophones to measure the pressure wavefield (P) and accelerometers to measure the particle acceleration vector (A). The latter represents the spatial gradient of pressure as derived through the particle equation of motion,  $\nabla P = -\rho A$ , where  $\rho$  is the fluid density [8].

#### 3.1. Reconstructing P from aliased $(P, P_v)$ data

An important problem is to reconstruct (interpolate) the total pressure wavefield P at any desired position in the crossline direction from sparse samples of itself and its crossline gradient. P is the sum of the upgoing and downgoing (ghost) wavefields. For this problem, the unknown signal is is  $s(f_k k_x k_y) = P(f_k k_x k_y)$ ; the measurement vector is

$$\boldsymbol{m}(t, x, y_l) = \begin{bmatrix} P(t, x, y_l) & P_y(t, x, y_l) \end{bmatrix}^l, \quad l = 1, 2, \cdots, L, \quad (7)$$

where  $P_y$  is the crossline gradient of the pressure wavefield; the number of streamers (*L*) is typically 8-12. The forward linear operator is

$$\boldsymbol{H}(f,k_x,k_y) = \begin{bmatrix} 1 & jk_y \end{bmatrix}^T.$$
(8)

Here, *f* is the temporal frequency;  $k_x$  and  $k_y$  are the inline and crossline wavenumbers, respectively. As the data are well sampled in the temporal (*t*) and inline (*x*) coordinates, we can operate the GMP algorithm outlined in Section 2 for fixed values of *f* and  $k_x$ . The particular form that GMP takes for this reconstruction problem is referred to as MIMAP (Multichannel Interpolation by Matching Pursuit) [9].

Fig. 3. Example with simple synthetics: close-up of a region of the t-y domain and f-k transforms of the whole dataset. (a, b) Input pressure, sampled at 75 m; (c, d) reconstruction using a sinc interpolator; (e, f) reconstruction using a multichannel sinc interpolator, also having as input the crossline gradients at the samples positions; (g, h) reconstruction with MIMAP, also having as input the crossline gradients at the samples positions.

Figure 3 shows a simple example reproducing linear events with energy up to 65 Hz and various incidence angles first decimated at 75 m and then reconstructed using different techniques. At every receiver position we modeled both the synthetic signal and its horizontal gradient. For the selected geometry, an event propagating horizontally generates first order alias at 10 Hz, and second order alias at 20 Hz, as shown in 2(b). Since MIMAP does not assume that the data comprise linear events in the implementation used for this example, the presence of high orders of aliasing presents a significant challenge for reconstruction.

To show the antialiasing capabilities of MIMAP, we interpolated the data with two standard techniques in addition to MIMAP: the sinc interpolation, and the multichannel sinc interpolation [7]. In Figure 3(a) we can see a region of the input time-space gather describing the pressure synthetics, sampled at 75 m, and the frequencywavenumber transform of the overall gather. The high order aliasing is clearly visible in the f-k domain (Fig. 3(b)). Figures 3(c) and 3(d) show the results of the singlecomponent conventional sinc interpolator, bandlimited in the spatial sampling bandwidth. As expected, only frequencies up to 10Hz are not aliased, and only the events with small incident angle are correctly interpolated (i.e., event at 2.6 s). Figures 3(e) and 3(f) show the result of the multichannel sinc interpolation, bandlimited to twice the spatial Nyquist. In this case, we can see that more events are reconstructed correctly in the *t*-y plot (e.g., events at 2.4s, 2.5s and 2.6s), and that all the events are reconstructed correctly up to 20 Hz. What is also interesting is that the multicomponent sinc seems to amplify the aliased events that cannot be reconstructed, as visible in the *f*-*k* gather above 20 Hz. Moreover, the shape of the region not affected by the alias, or affected by a first-order alias only, is clearly recognizable as the properly reconstructed area. Finally, in Figures 3(g) and 3(h), we can observe the results produced by MIMAP, and the removal of aliasing up to very high frequencies can be appreciated. All the events are well reconstructed.

# 3.2. Reconstructing $P^{up}$ from aliased $(P, P_y, P_z)$ data

Using *P*, *P<sub>y</sub>*, and *P<sub>z</sub>* data that can be recorded by a multimeasurement streamer, another and more challenging problem would be to reconstruct  $P^{up}$  at any desired position without having access to any direct samples of it. This is called the joint interpolation and deghosting problem [10], where the task of separating the wavefield into its down- and upgoing components is performed simultaneously with the task of reconstructing it at any desired position. For this problem, the unknown signal is  $s(f,k_x,k_y)=P^{up}(f,k_x,k_y)$ ; the measurement vector is

$$\boldsymbol{m}(t, x, y) = \left[ P(t, x, y) P_{y}(t, x, y) P_{z}(t, x, y) \right]^{T}, \ l = 1, 2, \cdots, L, (9)$$

and the forward linear operator that links the measurements to the unknown signal is the ghosting operator defined by

$$H(f,k_{x},k_{y}) = \left[ \left( 1 + \xi e^{j2k_{z}Z} \right) k_{y} \left( 1 + \xi e^{j2k_{z}Z} \right) jk_{z} \left( 1 - \xi e^{j2k_{z}Z} \right) \right]^{t}.$$
 (10)

Here,  $k_z$  is the vertical wavenumber, Z is the depth of the streamer, and  $\xi$  is the reflection coefficient of the sea

Fig. 4. Seismic synthetics in the 3D spectrum ( $f-k_x-k_y$ ) domain. (a) reference total pressure wavefield, sampled over a 25- x 25-m grid; (b) reference upgoing pressure wavefield, sampled over the same grid; (c) input total pressure wavefield at 150-m crossline spacing; (d) upgoing pressure wavefield, reconstructed over a 25- x 25-m grid by GMP, processing *P*, *P<sub>y</sub>*, and *P<sub>z</sub>* at 150 m in the crossline.

surface. Through the ghost model, the  $P_z$  component brings independent new information on the unknown upgoing wavefield, which is crucial for this application [10].

Figure 4 shows the application of GMP to synthetic data. The data set was created by finite-difference modeling and simulates a 3D survey over a complex geological structure. The source signature spectrum is flat up to 30Hz. The streamer depth is 50m; the depth was chosen to place the pressure ghost notch within the 30Hz bandwidth. Given P,  $P_{v}$ , and  $P_{z}$  data sampled at 150m and severely aliased, the reconstructed upgoing pressure wavefield sampled at the desired 25m interval show both the dealiasing and the deghosting capabilities of this approach. Figure 4(a) shows the  $f-k_x-k_y$  transform of the total pressure wavefield before decimation, with pressure sampled over a 25m x 25m spatial grid. We can recognize the lack of energy in the low wavenumbers in the 15Hz slice, and a circularly shaped notch in the 20Hz and 25Hz slices, due to the ghost: events not affected by the notch are still affected by the constructive interference of the ghost. Figure 4(b) shows the f-kx-ky transform of the reference upgoing pressure wavefield, sampled over a 25m x 25m spatial grid. The  $f-k_x$  $k_{\rm v}$  transform of the total pressure wavefield after decimation of the data to 150 m in the crossline direction is shown in Figure 4(c). Alias starts just above 5 Hz and the order of the alias grows with frequency. Figure 4(d) shows the  $f - k_x - k_y$ transform of the upgoing pressure wavefield reconstructed by GMP, to a 25m x 25m spatial grid. The ghost notch is filled and the dealiasing impact of GMP is evident if we compare the output shown here with the spectrum of the input in the previous. Comparison of Figures 4(b) and 3(d) confirms the accuracy of joint interpolation and deghosting achieved by GMP.

### 4. CONCLUSIONS

The problem of reconstructing a bandlimited signal from highly aliased multichannel samples was considered and Generalized Matching Pursuit (GMP) proposed as a solution. GMP models the signal as a sum of parametric basis functions that are matched to the data in a simultaneous and iterative fashion through application of the respective linear operators. Under quite general conditions GMP can reconstruct signals aliased by orders significantly higher than the number of measurements, including the notoriously difficult case of regular undersampling. We should emphasize that the results shown in this paper were obtained without using any priors

(e.g., constraints from low-frequency to high-frequency), which are often utilized to interpolate aliased data: the reconstructions were carried out without assumptions on events being planar. During the presentation we will show real data results, omitted here for lack of space.
